An ultra-thin silicon nitride (SiN_x) layer formed by catalytic chemical vapor deposition (Cat-CVD) is used to replace the Si dioxide (SiO_2) layer of a tunnel oxide passivated contact (TOPCon) solar cell. The passivation quality of crystalline Si (c-Si) with a stack of the ultra-thin SiN_x and n-type hydrogenated amorphous Si (a-Si:H) or microcrystalline Si ($\mu\text{c-Si:H}$), also formed by Cat-CVD, is significantly improved by annealing at 850 °C, probably due to the formation of a back surface field (BSF) layer. Cat-CVD SiN_x with thicknesses of up to 2.5 nm can have sufficient tunneling conduction. The ultra-thin SiN_x having functions of surface passivation and carrier tunneling, and the unification of the formation method for the tunnel SiN_x and conductive layers will lead to the realization of tunnel nitride passivated contact (TNPCon) solar cells.

1. Introduction

Tunnel oxide passivated contact (TOPCon), a kind of passivated contact for crystalline silicon (c-Si) solar cells, is known to have excellent passivation ability despite its simple structure consisting of an ultra-thin tunnel Si oxide (SiO_2) and a P-doped Si layer.¹⁻⁴⁾ The ultra-thin tunnel SiO_2 in the TOPCon structure is generally formed by ultraviolet-ozone (UV- O_3) oxidation, thermal oxidation, or wet-chemical oxidation.⁵⁻⁷⁾ For the tunnel passivated layer, SiO_2 is not the only option, and it has been confirmed that Si nitride (SiN_x) can also work well in passivated contact under appropriate conditions.⁸⁾

There are many methods to form thin tunnel SiN_x films, such as sputtering,⁹⁾ jet vapor deposition (JVD),^{10,11)} atomic layer deposition,¹²⁾ plasma-enhanced chemical vapor deposition (PECVD),¹³⁻¹⁵⁾ and direct nitridation,^{16,17)} some of which have been conventionally used in the industry of semiconductor devices.^{18,19)} Of a variety of methods,

1 catalytic CVD (Cat-CVD), often also referred to as hot-wire CVD (HWCVD), may be one
2 of the best ways for the formation of thin tunnel SiN_x .²⁰⁾ Cat-CVD is a method of depositing
3 thin films by decomposing gas molecules on a heated catalyzing wire such as tungsten and
4 tantalum.^{21–23)} Unlike in the case of PECVD, Cat-CVD can realize plasma-damage-free film
5 deposition, which is suitable for the formation of passivation films on c-Si. We have thus far
6 obtained an outstandingly low surface recombination velocity (SRV) below 5 cm/s when
7 mirror-polished n-type floating-zone (FZ) c-Si wafers are passivated by Cat-CVD SiN_x films
8 with a thickness of ~ 100 nm.²⁴⁾ We have also previously demonstrated a good passivation
9 quality of an ultra-thin Cat-CVD SiN_x film covered with a ~ 8 -nm-thick phosphorous (P)-
10 doped Si film, showing an effective minority carrier lifetime (τ_{eff}) of >400 μs .²⁰⁾

11 In this study, we propose a new passivated contact by replacing ultra-thin tunnel SiO_2 in
12 TOPCon with an ultra-thin SiN_x film, named tunnel nitride passivated contact (TNPCon).
13 Although similar structures have been reported,²⁵⁾ their SiN_x layers do not act as a tunneling
14 passivation film, which is fundamentally different from TNPCon. SiN_x can be formed by
15 one-side deposition by Cat-CVD^{26–29)}, which can be combined with the successive
16 deposition of a P-doped Si layer. As a result, the fabrication process of the cells can be
17 simplified. To investigate the performance of the new passivated contact,³⁰⁾ the passivation
18 quality of TNPCon was characterized based on minority carrier lifetime. We also evaluated
19 the property of majority carrier transport by resistance measurement. Through these
20 measurements, we demonstrated the feasibility of TNPCon for the passivation contact of c-
21 Si solar cells.

22

23 **2. Experimental procedures**

24 280 μm -thick, mirror-polished n-type 1–5 Ωcm (100)-oriented FZ Si wafers with a bulk
25 minority carrier lifetime of >10 ms were cleaved into 20×20 mm^2 pieces. All the substrates
26 were cleaned according to the RCA cleaning procedure,³¹⁾ then were dipped in 1%
27 hydrofluoric acid (HF) to remove oxide formed during SC-2. After the HF dipping, the
28 substrates were carried into a load lock chamber of a Cat-CVD system immediately. The
29 substrates were then pre-heated up to a target temperature of 200 $^\circ\text{C}$ in H_2 atmosphere at 30
30 Pa for 5 min before the deposition of SiN_x films. The Cat-CVD of SiN_x layers was performed

1 using a tungsten catalyzer heated at 1800 °C with a length of ~200 cm and a diameter of 0.5
2 mm placed at a distance of 12 cm from a substrate holder. The samples were set in face-
3 down configuration and four edges of each sample were contacted to the substrate holder.
4 The pressure in the chamber without gas flow was kept in a high vacuum of 10^{-6} Pa. SiN_x
5 layers were deposited symmetrically on both sides of the Si substrates. Except for the
6 investigation on SiN_x thickness dependence, all the SiN_x films were deposited for 10 s,
7 resulting in a SiN_x thickness of ~1.8 nm. Subsequent P-doped microcrystalline Si ($\mu\text{c-Si:H}$)
8 and amorphous Si (a-Si:H) layers with a thickness of ~20 nm were deposited in another Cat-
9 CVD chamber. $\mu\text{c-Si:H}$ is used mainly in this study, which was formed at a low deposition
10 rate (~4.0 nm/min) under a low SiH_4 flow rate and a high H_2 -dilution. a-Si:H films formed
11 at a deposition rate of ~8 nm/min were used for comparison to investigate how the doping
12 concentration of the P-doped Si layer affects the passivation quality of TNPCon. To obtain
13 P-doped $\mu\text{c-Si:H}$ and a-Si:H films with various thicknesses, the deposition duration was
14 systematically varied. The detailed deposition conditions of ultra-thin tunnel SiN_x and P-
15 doped Si layers are summarized in Table I. The thickness of SiN_x and P-doped Si layers were
16 measured on J. A. Woollam HS-190TM spectroscopic ellipsometer. Especially transmission
17 electron microscopy (TEM) images were acquired to confirm the thickness of ultra-thin
18 tunnel SiN_x films more accurately.

19 The samples with symmetrical TNPCon structures were put into a tube furnace and
20 annealed at 850 °C in N_2 atmosphere for 1 hour. This step is used for the crystallization of
21 precursor $\mu\text{c-Si:H}$ or a-Si:H films and for the diffusion of P in the doped Si layer into a c-Si
22 substrate, to be exact. The crystallization of $\mu\text{c-Si:H}$ and a-Si:H was confirmed by Raman
23 spectroscopy (not shown). In order to investigate the passivation quality of TNPCon on c-
24 Si, the τ_{eff} of the symmetrical samples was measured by microwave photoconductivity decay
25 ($\mu\text{-PCD}$) (Kobelco LTA-1510EP) using a laser pulse at a wavelength of 904 nm with a
26 photon density of $5 \times 10^{13} \text{ cm}^{-2}$ for the generation of excess carriers.

27 We prepared two types of structures for the evaluation of the contact resistance of TNPCon
28 structure. Ti/Ag electrodes consisting of ~20 nm-thick Ti and ~1 μm -thick Ag were deposited
29 by vacuum evaporation for both structures. For the structure for the qualitative evaluation of
30 contact resistance, both sides of the 1 cm \times 1 cm samples were fully covered with the Ti/Ag

1 electrodes. For the structure for transmission line method (TLM), patterned Ti/Ag electrodes
2 with various intervals were evaporated. Current density–voltage (J – V) curves of the samples
3 were measured in a semiconductor analyzer using Kelvin method for these samples to
4 evaluate the tunneling condition of TNPCon structure.

6 3. Results and discussion

7 3.1 Thickness dependence of ultra-thin tunnel SiN_x

8 Figure 1 shows the TEM images of $\mu\text{-Si:H/SiN}_x/\text{c-Si}$ structures, in which SiN_x films were
9 deposited for 10 and 30 s, respectively. SiN_x films deposited for 10 and 30 s are 1.7–1.9 nm
10 and 3.1–3.2 nm thick. Hence, the thicknesses of SiN_x films deposited for 20 and 45 s are
11 extrapolated to be ~ 2.5 and ~ 4.2 nm, respectively.

12 Figure 2 shows the J – V curves of the samples with various SiN_x thicknesses. In this
13 structure, $\mu\text{-Si:H}$ formed at a He-diluted PH_3 flow rate of 100 sccm was used as the
14 precursor of P-doped poly-Si. The samples with SiN_x with thicknesses of 1.8 and 2.5 nm
15 show a linear J – V curves and have resistances of 0.11 and 0.18 Ωcm^2 , respectively. On the
16 other hand, when the thickness of SiN_x increases to 3.2 nm or more, the J – V curves lose
17 linearity and resistances increased drastically. This significant change indicates that the
18 tunneling transport of electrons is suppressed as SiN_x thickness increases, and SiN_x with a
19 thickness of up to 2.5 nm has a sufficient carrier tunneling ability. A typical thickness of SiO_2
20 in TOPCon structure is ~ 1.5 nm, while the maximum thickness of SiN_x for carrier tunneling
21 was reported to be 2.0 nm.³²⁾ The difference between the maximum thickness for electron
22 tunneling in SiO_2 and SiN_x can be theoretically explained as the result of a lower conduction
23 band offset in $\text{SiN}_x/\text{c-Si}$ than in $\text{SiO}_2/\text{c-Si}$.

24 Figure 3 shows the τ_{eff} of the samples before and after annealing as a function of SiN_x
25 thickness. The same P-doped layer as the experiment for Fig. 2 was also used in this structure.
26 All the τ_{eff} values increase by annealing, except for the reference sample without a SiN_x layer.
27 This clearly indicates that the ultra-thin SiN_x layer works as a passivation layer. The
28 maximum τ_{eff} of ~ 0.8 ms was obtained by using an ultra-thin SiN_x with a thickness of 1.8
29 nm after annealing. On the other hand, as the SiN_x becomes thicker, τ_{eff} after annealing
30 decreases. We also observed a decrease in substrate resistivity (ρ_{sub}), measured on a quasi-

1 steady-state photoconductance (QSSPC) system, with decreasing SiN_x thickness. During
2 annealing at 850 °C, phosphorus atoms in the doped Si layer are expected to diffuse through
3 the SiN_x layer into c-Si substrate to form a heavily doped n-type Si ($\text{n}^+\text{-Si}$) layer, which can
4 explain the decrease of ρ_{sub} . This $\text{n}^+\text{-Si}$ layer can act as back surface field (BSF), by which
5 its passivation ability is improved. The improvement in τ_{eff} can be explained by the formation
6 of the BSF layer. SiN_x acts as a barrier layer against P-diffusion, and the formation of the
7 BSF layer was suppressed in the samples with thicker SiN_x .

9 3.2 Doping concentration of P-doped Si

10 The doping concentration of the P-doped Si on SiN_x can be a crucial factor for the
11 properties of TNPCon since phosphorus in the doped Si layer contributes to the formation
12 of BSF. Here, we compared two types of doped Si precursors: a-Si:H and $\mu\text{c-Si:H}$. Figure 4
13 shows the τ_{eff} of the samples with a SiN_x thickness of 1.8 nm as a function of He-diluted PH_3
14 flow rate. Within a certain range, PH_3 flow rate and phosphorus doping concentration are
15 positively correlated. At the beginning of the increase in doping concentration, both types of
16 Si layers show the same tendency for τ_{eff} improvement, which is consistent with our
17 hypothesis that SiN_x /BSF enhances passivation. TNPCon structures after annealing can
18 realize an excellent passivation ability with a τ_{eff} of ~ 0.8 ms, independent of the types of P-
19 doped Si precursors. τ_{eff} then turns to decrease with further increase in PH_3 flow rate, the
20 reason for which is unclear at present.

21 Here we also discuss the τ_{eff} of the samples before high temperature annealing, although
22 this is not the main purpose of this study. In general, an a-Si:H layer shows better passivation
23 ability than $\mu\text{c-Si:H}$ layer, but the difference in τ_{eff} disappears by performing annealing. One
24 plausible explanation is that a-Si:H and $\mu\text{c-Si:H}$ have different passivation mechanisms
25 before annealing, chemical passivation of dangling bonds on c-Si surfaces, while the
26 passivation mechanism is unified into SiN_x /BSF enhanced passivation by high temperature
27 annealing. Combined with the above phenomenon, it is reasonable to speculate that
28 phosphorus doping concentration is one dominating factor in the passivation quality of
29 TNPCon.

3.3 Carrier transport performance of TNPCon

Not only the high passivation quality but good electron transport performance is necessary for the solar cell application of TNPCon. Figure 5 shows the total resistance of the samples for TLM measurement with a SiN_x thickness of 1.8 nm as a function of electrodes interval. All the data points are on the linear fitting line shown as a red dotted line, and the extrapolated zero-length resistance corresponds to the twice of the contact resistance (R_C). R_C of TNPCon is estimated to be only $0.014 \text{ } \Omega\text{cm}^2$, which is low enough for the utilization to solar cells.

The bare c-Si wafer used in this study has a ρ_{sub} of $\sim 3.5 \text{ } \Omega\text{cm}$, measured on a QSSPC system. We can also evaluate ρ_{sub} from the slope of the linear fitting line. In Figure 6, ρ_{sub} is estimated to be $1.03 \text{ } \Omega\text{cm}$, much lower than bare c-Si wafer. In the TLM test, current flows laterally parallel to the plane of the substrate. This indicates that the BSF layer, formed during high temperature annealing by the diffusion of phosphorus atoms from the Si layer, works as a lateral carrier conduction path to reduce a resistance. The lower ρ_{sub} of the sample than that of the Si wafer is a clear experimental evidence for the formation of the BSF layer. Note that lateral carrier flow in poly-Si may be negligible due to air exposure of poly-Si surfaces and resulting carrier depletion by Fermi-level pinning³³.

We also investigated the impact of the thickness of phosphorus-doped Si layer on τ_{eff} . Figure 6 shows the τ_{eff} as a function of the thickness of P-doped Si layer. The P-doped layer here before annealing was $\sim 25\text{-nm-thick } \mu\text{c-Si:H}$ deposited at a PH_3 flow rate of 100 sccm. When the thickness of a P-doped Si layer is $>10 \text{ nm}$, τ_{eff} is almost independent of the thickness of the P-doped Si layer. On the other hand, increasing the thickness of P-doped Si layer does not influence the total resistance due to its low resistivity ($\sim 10^{-2} \text{ } \Omega\text{cm}$). We can thus conclude that an extremely thick P-doped Si layer is not necessary for the improvement of the passivation quality of TNPCon.

4. Conclusions

We realized a new type of passivated contact called TNPCon by Cat-CVD with functions of high surface passivation ability and sufficient carrier transport performance. The maximum thickness of Cat-CVD SiN_x for efficient tunneling transport is found to be as thick

1 as ~ 2.5 nm. TNPCon shows high passivation ability with a τ_{eff} of ~ 0.8 ms after high
2 temperature annealing, owing to the formation of a BSF layer as well as the passivation by
3 the ultra-thin SiN_x . Contact resistance of TNPCon is estimated to be $0.014 \Omega\text{cm}^2$, which is
4 low enough to be used for c-Si solar cells. TNPCon is therefore considered as a credible
5 alternative to conventional TOPCon structures.
